Periapical abscess of a lower central incisor associated with a tongue piercing: A case report

Mehmet Oztel* and Paul G. Birch

Introduction

Piercings of the oral cavity has become increasingly popular amongst youth in western society, with some studies indicating a prevalence of 5.2% [1]. This popularity in certain fashion trends presents a growing problem for oral health professionals due to emerging evidence of its associated oral complications.

Gingival recession, tooth wear and fracture are the most frequently described complications of oral piercings [2,3]. Patients with tongue or labial piercings appeared to have the greatest incidence of such complications, particularly if they described a habit of knocking, biting or tapping of the piercing against the oral hard tissues [4,5]. Other oral complications include gingival inflammation, ulceration and periodontitis [5-8]. Although systemic complications are much more rare, the consequences of such complications can result in significant morbidity and mortality. These complications include Ludwig’s angina, anaphylaxis, cerebral abscess, endocarditis, and hepatitis/HIV infection [5,9].

This case describes a periapical lesion of tooth 41 associated with a large metallic tongue piercing, a complication which to our knowledge, has not been described in the literature previously.

Case description and results

A 29-year-old female presented complaining of an extruded and mobile tooth 41 (Figure 1). Patient first noticed the tooth was slightly extruded over a year ago and was concerned about it becoming increasingly mobile since. She denied any pain or symptoms associated with the tooth. Patient could not recall any history of trauma though mentioned she had worn a large metal tongue piercing for the past 11 years (Figure 2). Although she denied any habit of biting or tapping of the piercing against the teeth, she stated that it would occasionally hit the lower anterior teeth when moving her tongue or brushing her teeth.

Clinical examination revealed grade two mobility of tooth 41. The buccal and lingual gingival mucosa were slightly inflamed and displayed 5 mm of recession on the buccal surface, and 6 mm of recession on the lingual surface. A wear facet was evident on the cingulum area of tooth 41. There was no evidence of any caries, cracks, fractures or discolouration. The tooth was not tender to percussion and thermal testing revealed a sluggish yet positive response to cold stimuli.

A periapical radiograph was taken showing large periapical radiolucency associated with tooth 41 (Figure 3). Overall the alveolar crest appeared intact.

The radiographic and clinical findings suggested that the periapical lesion was of endodontic origin. The large metallic barbell was determined to be the causative agent of the dental injury.

The first and perhaps most important step in treatment was removal of the underlying cause. After careful explanation of her diagnosis and the risks of the oral piercing, the patient was happy to remove it. Root canal therapy was then completed on tooth 41 and the patient asked to return for review in 3 months.

Discussion

The development of gingival recession or tooth fracture following traumatic injury from an oral piercing has been well documented in the literature [2,3]. To our knowledge the formation of a periapical lesion...
This case highlights another complication brought on by the long-term use of large oral piercings. Examination of such patients should involve evaluation for any obvious signs of trauma and also for more subtle clinical signs like wear facets. These patients should be discouraged from wearing oral piercings and if not possible, oral health professionals should be prepared to provide information regarding the potential for complications and expensive dental treatment.
