Assessment of hemodialysis effect on left ventricular mechanical dyssynchrony by tissue synchronization imaging

Waleed Abdou Ibrahim Hamed*, Mahmoud Kamel and Rehab Yaseen

Department of Cardiology, Menoufia University, Egypt

Abstract

Background: Abnormal myocardial loading can contribute to left ventricular (LV) mechanical dyssynchrony in patients with end-stage renal disease (ESRD) and may be a factor contributing to the high incidence of cardiac deaths in these patients. The study aims to evaluate the possible presence of LV dyssynchrony in ESRD patients, and acute effect of hemodialysis (HD) on LV synchronicity using tissue synchronization imaging (TSI).

Methods: Twenty patients with ESRD (11 males and 9 females) with mean age 63.1±4.41 were underwent echocardiographic examination before and immediately after a single HD session. Echocardiography was done using two dimensional strain imaging, global longitudinal systolic strain was measured in the apical views. LV mechanical dyssynchrony was assessed using TSI analysis enabling the retrieval of regional intraventricular systolic delay data. LV mechanical dyssynchrony was defined as a maximum regional difference in time to peak systolic velocity >105 ms and/or all segments standard deviation (SD) “dyssynchrony index” >32.6 ms.

Results: All patients had dyssynchronous LV segments before HD. A single HD session induced decrease in the global LV systolic strain from -19.65 ± 3.03 to -16.29 ± 2.75 (P<0.001), it also reduced the all segments maximum difference from 123.65 ± 33.94 to 102.60 ± 20.84 (P<0.001), the all segments SD was also reduced from 52.2 ± 12.31 to 40.15 ± 8.51 (P<0.001). Furthermore, the systolic dyssynchrony parameters were positively related to the LVEDD.

Conclusion: LV dyssynchrony is frequently present in patients with ESRD. The severity of LV dyssynchrony decreases after a single session of HD suggesting the deleterious effect of volume overload and may be the accumulating toxins on LV myocardium in such patients.

Introduction

Cardiac disease is the major cause of premature deaths in hemodialysis (HD) patients, accounting for 43% of all-cause mortality [1,2], and the frequency of sudden cardiac death is almost 50% higher after the long dialysis interval [3]. A factor that may have a potential to contribute to the high incidence of cardiac deaths in end-stage renal disease (ESRD) patients is intra-left ventricular (LV) mechanical dyssynchrony, a disorder that markedly affects systolic performance, cardiac electrophysiology, regional myocardial perfusion and metabolism [4,5].

Abnormal loading conditions such as excessive volume overload can worsen LV mechanical dyssynchrony by intensifying imbalances in the regional stretching and shortening of myocardial fibers following abnormal stress to myocardial tissue, especially in patients with ESRD requiring chronic HD therapy [6].

The accurate identification of LV dyssynchrony has been considerably improved by the introduction of a new diagnostic echocardiographic technique called tissue synchronization imaging (TSI) [7]. TSI provides an advanced analysis of synchronicity of myocardial motion based on the automatic detection of the time to peak systolic myocardial velocity at any discrete point within the myocardial wall and subsequent translation of the synchronicity data into color-coded maps. The regions of dyssynchrony contracting LV myocardium can thus be easily and quickly identified and quantified, and the obtained information allows better selection of patients for cardiac resynchronization therapy (CRT) and better therapeutic results [8,9]. The occurrence of intra-LV dyssynchrony has been described not only in patients with heart failure but also in individuals with LV hypertrophy (LVH) caused by pressure overload [10]. LVH has been shown to be present in 74–78% of patients on dialysis [11-13] and constitutes an independent risk factor for mortality in this patient category [14]. LVH, together with other cardiac abnormalities such...
as LV dilatation and arrhythmias [15,16] that often occur in ESRD patients [4], may by themselves induce and also be worsened by LV dysynchrony. However, a possible occurrence of LV dysynchrony in ESRD patients without heart failure and normal QRS duration has not yet been fully assessed.

There are significant numbers of studies that have shown the usefulness of tissue Doppler imaging (TDI) in identifying diastolic dysfunction in chronic kidney disease (CKD) and ESRD patients [17-19]. Unfortunately, TDI is an angle-dependent study and has a high inter-observer variability beside it requires expert interpretation. Two dimensional speckle tracking echocardiography (2D-STE) is a novel method of calculating the ventricular strain pattern that provides a reliable estimation of ventricular strain analysis in a shorter duration of time than TDI. It provides an angle-independent assessment and has less inter-observer variability [20,21]. There are very few studies of ventricular strain evaluation with 2D-STE in CKD and ESRD patients [20,22,23].

The objective of this study was to evaluate the possible presence of LV dysynchrony in ESRD patients, and acute effect of hemodialysis (HD) on LV synchronicity using tissue synchronization imaging (TSI).

**Patients and methods**

**Patient selection**

The study included twenty patients with ESRD (11 male and 9 female) with mean age 63.1 ± 4.41, all the included patients didn’t show any clinical or electrocardiographic (ECC) signs of coronary artery disease and didn’t show wide QRS duration in the surface ECG, the conventional echocardiographic screening showed normal ejection fraction (EF) and no regional wall motion abnormalities. The entire studied population was enrolled after informed consent was obtained and after approval of the ethics committee of the university hospitals was obtained.

**Hemodialysis**

All patients were on maintenance regular conventional hemodialysis, 4-hours session, 3 times per week for at least 6 month in the dialysis unit of Menoufiya University Hospital, using hemodialysis machine with volumetric control (Fresenius Medical Care (4008B) with polysulfone filters (Fresenius F6). The standard dialysis bath consisted of sodium, 140 mEq/L; potassium, 2 mEq/L; calcium, 3 mEq/L; and bicarbonate, 35 mEq/L. The ultrafiltration rate was programmed to achieve a satisfactory image. The software then tracked the myocardial peak systolic velocity (S max), early (E’) and late (A’) diastolic velocities were measured.

**Conventional echocardiography**

Echocardiographic examination was done by using the commercially available Vivid 9, General Electric Healthcare, GE Vingmed, Norway equipped with a 1.7-4 MHz phased-array transducer. Echocardiographic imaging were obtained in the parasternal long- and short-axis, and apical two, three and four-chamber views using standard transducer positions. LV end-diastolic diameter (LVEDD), LV end-systolic diameter (LVESD), septal (IVS) and posterior wall (PW) and relative wall thickness (RWT) in diastole, ejection fraction (EF%), and left atrial (LA) diameter were measured in accordance with the recommendations of the American Society of Echocardiography [25]. Pulsed and Continuous-wave Doppler was used for valvular assessment, Peak early (E) and late (A) transmitral filling velocities were measured from mitral inflow velocities.

Left ventricular pulsed-Tissue Doppler indices were acquired, using a 5-mm sample volume, placed on the four sites of mitral annulus in apical four and apical two views. Frame rate was selected between 120 and 180 Hz and average values of 3–5 consecutive heart beats were recorded. The myocardial peak systolic velocity (S max), early (E’) and late (A’ ) diastolic velocities were measured.

**Longitudinal strain measurement**

For measurement of LV longitudinal strain, two dimensional images from the apical four-chamber, two-chamber and three-chamber views were obtained, Frame rate was selected between 40–90 or at least 40% of HR.

All recordings included at least three cardiac cycles were digitally stored for off-line analysis. Stored images were opened by the machine software, which automatically brings up the end-systolic frame of the cardiac cycle. At the end-systolic frame, endocardial border was traced manually, beginning at one end of the mitral annulus and ending at the other end.

The software then generated a region-of-interest (ROI) including the entire myocardial thickness. The ROI was manually adjusted to achieve a satisfactory image. The software then tracked the myocardial speckles frame by frame and generated moving images displaying the tracking.

Careful visual inspection of the moving image was done to determine the adequacy of the tracking. If the tracking was not accurate, readjustment of the ROI or selection of a new ROI was done.

The software divided the LV myocardium into six segments and generated segmental and global longitudinal strain curves. As the myocardium shortens in longitudinal direction during systole, the longitudinal strain curves are displayed below the baseline.

The apical long-axis image (i.e., apical three-chamber view) was first image to be analyzed. In this view, the movement of aortic valve leaflets helps in timing the aortic valve closure which is essential for the software to be able to perform the deformation analysis [11].

The same process was then repeated with the apical four chamber and two-chamber images also. The strain values for all the segments were recorded and averaged to obtain the global longitudinal strain.
(GS). The ultrasound system also provided Bull’s eye display of the regional and global longitudinal strain.

**Tissue synchronization imaging**

Tissue synchronization software processes the acquired TVI data and provides automatic detection of the time to peak systolic velocity (PSV) at any discrete point within the wall. The obtained temporal data are translated into color coded maps of LV contraction synchronicity with color coding ranges from green (earliest), yellow, orange, to red (latest) giving a detailed quantitative information about the regions of dys synchronously contracting LV myocardium. A color-coded image of synchronicity of LV contraction is thus created. The analyzed systolic interval was set by default to start 60 ms after the beginning of electrocardiographic R wave and to end 200 ms after the closure of the aortic valve, thus including possible postsystolic contraction. Prior to the analysis, the TSI images were frozen and scrolled to the end of systole to ensure adequate positioning of regions of interest within the myocardial wall for the whole systole. Subsequently, circular regions of interest (diameter 2 mm) were placed manually on the basal and midventricular myocardium of the opposing LV walls in apical 2, apical 4 and apical long axis views. Intraventricular mechanical dys synchrony of a LV segment was defined according to Perry, *et al.* [26] as all segment maximum difference (ASMD) >105 ms, ASMD is the difference between the longest and the shortest time to PSV among all the evaluated 12 segments. Dys synchrony index was used also to define intraventricular dys synchrony of the LV which is the standard deviation of the time to PSV of the 12 LV segments. LV systolic dysynchrony is defined as dys synchrony index >32.6 msec [27].

**Statistical analysis**

Data were collected, tabulated, statistically analyzed by computer using SPSS version 20, two types of statistics were done:  
1- Descriptive statistics: Quantitative data are expressed to measure the central tendency of data and diversion around the mean, mean (x) and standard deviation (SD). Qualitative data expressed in number and percentage.
2- Analytic statistics: paired t test was used to compare between quantitative normally distributed data pre and post within the same group

Wilcoxon signed rank test was used to compare between quantitative not normally distributed data pre and post within the same group

P value > 0.05 was considered statistically non-significant.

P value ≤ 0.05 was considered statistically significant.

P value ≤ 0.001 was considered statistically highly significant.

**Results**

**Subjects’ clinical and biochemical data:** Table 1 summarizes the clinical and biochemical data of the studied ESRD patients, the study included 20 patients (11 males and 9 females) with mean age 63.1 ± 4.41. all the patients were hypertensive while 11 patients were diabetics and 7 patients were smoker.

Body weight was significantly reduced after HD, both serum potassium and serum PO4 were also reduced significantly after HD, while both serum Na and serum Ca showed no significant difference as shown in Table 2.

**Standard echocardiographic variables:** All patients had normal LVEDD, EF and FS, they all showed concentric LVH with RWT >0.45. As shown in Table 3, HD resulted in significant decrease in LVEDD, LVEF, FS, IVS, PW, LVE SD, ASMD, AP2S, AP3S, ADTI, EDTI, E/A, E, IVS, PO4, K, Ca and Na, while both serum Na and serum Ca showed no significant difference as shown in Table 2.

**Controlled Dis Ther, 2016 doi: 10.15761/VDT.1000105 Volume 1(1): 3-7**
LVESD and LA diameter, while the myocardial systolic velocity ($S_{\text{max}}$) increased significantly after HD. On the other hand, EF, FS, LV thickness and RWT didn’t change significantly after HD. As regard diastolic variables, there was a significant decrease after HD in the mitral A velocity, while the mitral E velocity was decreased but the change didn’t reach a statistical significant level. Both myocardial E’ and A’ velocity values were significantly increased after HD.

**Longitudinal strain values**: HD resulted in significant decrease in longitudinal strain values in apical 4, apical 2 and apical long axis views. The global longitudinal strain value was significantly decreased after HD from $-19.65 \pm 3.03$ to $-16.29 \pm 2.75$ (P<0.001) (Table 3, Figures 1 and 2).

**Intra-left ventricular synchronicity**: All patients showed intra-LV asynchrony before HD (ASMD $123.65 \pm 33.94$; dyssynchrony index $52.2 \pm 12.31$; Table 3). HD caused a significant decrease in ASMD from $123.65 \pm 33.94$ to $102.60 \pm 20.84$, P<0.001 (Table 3 and Figure 3). Though the value of dyssynchrony index didn’t fall below 32.6 after HD [which is the cut off value of dyssynchrony index as described by Yu CM, *et al.* [27], but it decreased significantly from $52.2 \pm 12.31$ to $40.15 \pm 8.51$, P<0.001 (Table 3 and Figure 3). Furthermore, it has been shown that the LV synchronicity parameters in the form of ASMD and dyssynchrony index showed a significant positive relation with LVEDD while it showed no significant relation with serum electrolyte levels (Table 4, Figures 4 and 5).

**Discussion**

In this study, we evaluated the effect of acute preload reduction after a HD session on LV mechanics in patients with ESRD. The obtained results indicate that Intra-LV dyssynchrony is present in patients with ESRD and decreases significantly after a HD session. Furthermore, the severity of disturbance in intraventricular synchronicity is related positively to the LVEDD.

CKD patients, particularly those with ESRD, are at much higher risk for myocardial dysfunction and mortality. Therefore, identifying the effect of acute preload reduction on LV mechanics is clinically important. The findings of this study suggest that HD causes a significant decrease in LV longitudinal strain and dyssynchrony index, which may contribute to the improvement of LV function in patients with ESRD. Further studies are needed to investigate the long-term effects of HD on LV mechanics and the potential mechanisms underlying these changes.

risk of CVD in comparison with the age- and sex-matched general population, with increased prevalence of coronary artery disease, small vessel disease, silent myocardial ischaemia, complex arrhythmias [28], LVH, valvar calcifications [29] and arteriosclerosis [30]. CVD is a major cause of morbidity and mortality in dialysis patients, accounting for almost 40% of hospitalisations and 79-80% reduction in life expectancy [31,32].

The existence of LV mechanical dyssynchrony may have the potential to contribute to the high incidence of cardiac events or deaths in patients with ESRD receiving HD therapy since the non-uniformity of LV contraction impairs systolic performance. Therefore, it is clinically important to identify LV mechanical dyssynchrony and to address its underlying mechanisms in such a population. It is widely recognized that abnormal electrical activation sequences of the heart can induce the abnormal onset of myocardial contraction resulting in LV mechanical dyssynchrony [33,34]. However, LV mechanical dyssynchrony can be caused not only by abnormal electrical activation but also by the heterogeneity of myocardial tissue damage and the non-uniformity of the ventricular wall structure [35]. Furthermore, significant mechanical dyssynchrony is usually absent in 30-58% of patients with QRS duration >120 ms [7,26,36,37], being at the same time present in 65% of individuals with QRS<120 ms [26] our results went in the same direction as we found that intra-LV dysynchrony is present in patients with ESRD despite having normal QRS duration.

The TSI technique is a novel echocardiographic imaging modality that analyzes myocardial tissue velocity signals and provides the timing of regional peak systolic velocities in relation to the onset of depolarization. The method has been proved to be reliable and reproducible [9,26] and its capacity to identify significant systolic dyssynchrony and thereby predict a positive response to CRT has been found to be superior to that of QRS duration criteria [9,26,38].

The impact of CKD and HD on LV function was assessed by Liu et al who examined 97 patients with ESRD and 56 control using 2D speckle tracking echocardiography, and he concluded that CKD and ESRD patients had more negative global ventricular strain compared to controls in order to maintain similar EF [22]. Similarly, we found that the longitudinal strain values in apical views and the global LV systolic strain were more negative in our patients before dialysis and these values were significantly reduced after the HD session.

The definition of LV dysynchrony in the present study was based on the cutoff value proposed by Perry et al, who studied a cohort of 100 volunteers with normal LV systolic function and normal QRS duration [22] The mean level of dysynchrony in these individuals was found to be 47 ± 29 ms that gives the mean value equal to 105 ms as the cutoff for
assessed by Hyashi,
of a single HD session on LV mechanical dyssynchrony was also
HD dramatically improved the radial LV dyssynchrony [6]. The effect
associated with longitudinal and radial LV dyssynchronies, and that
echocardiography, and he concluded that patients with ESRD were
dyssynchrony in 23 patients with ESRD using 2D speckle tracking
a significant dyssynchrony of LV during systole [26].

Murata, et al. [6] assessed the role of HD on LV mechanical
dysynchrony in 23 patients with ESRD using 2D speckle tracking
echocardiography, and he concluded that patients with ESRD were
associated with longitudinal and radial LV dyssynchronies, and that
HD dramatically improved the radial LV dyssynchrony [6]. The effect
of a single HD session on LV mechanical dyssynchrony was also
assessed by Hyashi, et al. [35] using TSI technique, and he found that
every examined patients had LV dyssynchrony before HD and the
HD session caused complete normalization in LV synchronicity in
23% of the patients and a significant decrease in the average maximal
systolic LV mechanical delay. Furthermore, the percentage of delayed
LV segments before HD was positively related to LVEDD [35]. Our
results went in parallel with those findings, as we found that all our
patients showed LV dyssynchrony before HD which was improved
significantly after a single session of HD. In addition, the parameters
used to assess the LV dyssynchrony were positively related significantly
to the LVEDD, whereas they showed no significant relation with the
serum electrolytes level denoting that the detected LV dyssynchrony
in ESRD before HD was not influenced by the electrolyte disturbances
commonly seen in such patients and it is mainly affected by the LV
volume overload before HD.

It has been demonstrated in animal studies and experiments in
humans that sustained stretching of myocardial fibres due to increased
ventricular loading induces shortening of the myocardial action
potential and effective refractory time, and increase in activation time
and dispersion of action potential duration. Even if the results of some
studies in animals challenge any significant impact of load alterations
on the outcome of the contraction–excitation interaction under normal
conditions, changes in loading conditions may be of significantly
greater electrophysiological implication under pathological conditions
that may distort the normal mechano-electrical feedback mechanism
[39-41].

Mechanical LV dyssynchrony has marked deleterious effects on
ventricular pump function leading to prolonged contraction and
reduced ejection time, delayed relaxation with reduced diastolic filling
time, mitral regurgitation [5,41] and arrhythmia susceptibility [4].

Similar effects can be expected in ESRD patients and the occurrence
of LV dyssynchrony in this population is considered an important risk
factor and bad prognostic sign [36,42].

In conclusion, the result of the present study indicate that intra-
LV mechanical dyssynchrony is present in patient with ESRD and this
dysynchrony can be significantly normalized by a single HD session
and it correlates positively with LVEDD suggesting the deleterious
effect of volume overload and may be the accumulating toxins on LV
myocardium in patients with ESRD.
