Abstract

Background: In the selection of an appropriate IUD little consideration is placed on adequacy of fit. Properly fitting IUDs will likely lead to less adverse effects or patient discomfort resulting in enhanced continuation of use.

Methods: A multicenter study conducted at 3 centers in 152 nulliparous women, to measure the maximal width of the uterine cavity using 3D ultrasound.

Results: Measurements were performed by experienced sonographists. The mean width of the uterine cavity in the fundus was 21.6 mm (range 6.0 - 40.0 mm). The median value was 22.0 mm and the IQR 18.0 - 24.8 mm, respectively. Eighty-two % of women had a uterine cavity width between 15 mm and 28 mm, 40% <20 mm and 6.6% <15 mm, respectively.

Discussion: Uterine cavities in nulliparous women are narrow and rarely wide enough to fit conventional IUDs. Gross discrepancy between the IUD and the uterine cavity leads to side effects (e.g., expulsion, embedment, bleeding, pain) and early discontinuation. Historically, devices too large for the uterine cavity have been routinely inserted which may account for their 5 year continuation rates being only 40 to 50%. Our study suggests that 3D sonography is a precise method to measure the width of the uterine cavity (although 2D may also be suitable) and may result in the selection of a suitable IUD to maximize continuation of use. Measurement of the cavity width is not necessary with a frameless IUD.

results likely as a consequence of using IUDs that did not fit properly. Precisely these young women are most disadvantaged by the occurrence of an unintended pregnancy caused by failure of the IUD [8-13]. Despite the many advantages for using IUDs, the continuation rates of the major IUDs used worldwide (Mirena, Bayer Healthcare, Germany and TCu380A/Paragard, Teva Pharmaceuticals, USA) for 5 years of use is only 50% and 40%, respectively [14]. Optimization in IUD selection is clearly required. This study of the width of the uterine cavity in nulliparous women was undertaken to explain the geometric foundation of IUD side effects which may lead to premature discontinuation.

Materials and methods

This non-intervention ultrasound study was conducted by 3 different investigators in Germany and Switzerland. All patients were recruited from a pool of mostly young women either requesting IUD contraception, or who already use an intrauterine contraceptive and are requesting a replacement, or who presented with IUD problems. Transvaginal 3D ultrasound measurements were done at any time during the menstrual cycle. The coronal view of the uterus is particularly well-suited to measure the width of the cavity and to demonstrate the relationship between the entire IUD and the uterine cavity [5]. The uterine cavity width is the distance between the two internal tubal ostia. All investigators used fully optimized and calibrated ultrasonographic equipment.

The study intended to determine the variability in the maximal fundal size in a large group of nulliparous women irrespective of age, body weight or other demographic information.

Data analysis

All 3D coronal images were saved for review. Individual investigators determined the maximal transverse fundal width for their respective patient populations. The findings were collated and all pertinent data included in an Excel spread sheet. Upon study completion the findings were subjected to statistical analysis by an independent statistician, which was performed using R V.3.3.0 (R Foundation for Statistical Computing, Vienna, Austria). Besides descriptive parameters, data were analyzed with the nonparametric Mann-Whitney U test and Kruskal-Wallis test and parametric ANOVA. The significance level was set at α = 0.05 [15].

Results

One hundred and fifty-two (152) nulliparous women participated in this study. The mean age was 25.5 years (SD 5.9 y, range 15-48 y). Figure 1 illustrates the individual patient data. Maximal uterine cavity widths ranged from a low of 6 mm to a maximum of 40 mm.

The mean maximal fundal width was found to be 21.6 mm (SD 5.1 mm). Forty % of uterine cavities were less than 20 mm wide; 6.6% less than 15 mm; and 0.7% less than 10 mm, respectively. Only 3 subjects or 2.0% had uterine widths greater than 32 mm. The interquartile range shows that 50% of uterine cavities in this group are between 18.0 mm and 24.8 mm wide, respectively. In our group 82% of patients had a uterine cavity width between 15 mm and 28 mm, respectively.

Figure 2 shows the fundal transverse diameter and range per investigator. Minor, non-significant differences were seen between the investigators (Kruskal-Wallis ANOVA, P = 0.575 [NS]).

Table 1 shows the 3D results.

Discussion

The use of long-acting reversible contraceptive methods (LARC) are considered of major importance in order to reduce the global
Nolte K (2016) A multicenter study assessing uterine cavity width in over 150 nulliparous women with IUD or seeking IUD insertion using 3D sonography

Discontinuation rates after 6-12 months of use of 40 to 50% are not unusual in nulliparous women. One recent study demonstrated that over 50% of the women will have maximal uterine widths >1 full cm narrower than the size of Mirena or TCu380A (32 mm). Unfortunately, the optimal IUD size for a specific woman is presently unknown. The muscular nature of the uterus itself may allow for insertion of a larger size device because of its ability to accommodate and is apparently what has been occurring historically in the clinic. Logic suggests that consequences, likely negative, will occur to the patient some of which may result in discontinuation or possibly more drastic medical interventions. With respect to conventional framed T-shaped systems, the precise IUD which will elicit maximal contraceptive advantages of IUDs with a subpopulation of women failing to consider them as viable options. In addition, the wasted expense of the IUD and the burden of insertion fails to provide the patient and third party payers with maximal economic benefit. Providers of IUDs should realize that the only way to obtain comfort during IUD use, and high user continuation, is by using an IUD that is not substantially wider than the width of the uterine cavity.

A growing body of research and clinical evidence is accumulating demonstrating that the uterine cavity for the majority of women is much smaller than many of the IUDs frequently used. A recent 2D ultrasound study conducted in nulliparous women found that about two thirds had a uterine cavity width of less than 24.4 mm. Ultrasound measurement in this group of 165 nulliparous women ranged between 13 and 35 mm [18]. Studies conducted by Kurz in Germany in the 1980s using a measuring instrument inserted in the uterus found a mean fundal transverse diameter in nulliparous women with age between 15 and 39 years of age of between 24 and 25 mm [19]. Our study is in agreement with these previous findings yielding a mean width of 21.6 mm. Surprisingly we found uterine cavities as narrow as 6 mm with 6.6% of the women being below 15 mm. This finding is significant when one realizes that if a device is inserted unknowingly in these women it will be almost 2 cm larger than her cavity itself. Even our mean findings of 21.6 mm demonstrates that over 50% of the women will have maximal uterine widths >1 full cm narrower than the size of Mirena or TCu380A (32 mm). Unfortunately, the optimal IUD size for a specific woman is presently unknown. The muscular nature of the uterus itself may allow for insertion of a larger size device because of its ability to accommodate and is apparently what has been occurring historically in the clinic. Logic suggests that consequences, likely negative, will occur to the patient some of which may result in discontinuation or possibly more drastic medical interventions. With respect to conventional framed T-shaped systems, the precise IUD which will elicit maximal

“epidemic” of unintended pregnancies, particularly in young women, as they are highly effective and not subject to daily concordance [16]. When viewed in relationship to other contraceptive options, many clinicians and researchers alike view IUDs as the almost near perfect contraceptive system. If true, then why do women using conventional T-shape LNG devices such as Mirena and Leveosert/Liletta (Actavis, USA) or the copper IUD TCu380A/Paragard fail to use them for their full effective lifespan beyond simply their desire to conceive? Typical discontinuation rates for medical reasons on average for these devices are 10-15% annually [14]. Medical reasons such as cramping, pain, bleeding are the principal reasons that many women discontinue using IUDs. Although still definitively unproven it appears obvious that incompatibility of the IUD itself with the uterine cavity is a significant contributory factor.

Nearly 50 years ago, researchers stressed the importance of an optimal interrelationship between the IUD and the uterine cavity as fewer side effects and greater acceptability would thereby be promoted. This study demonstrates the great variation in fundal width of uterine cavities (Figure 3).

Great disparity between the size of the IUD and the uterine cavity will often lead to early removal of the device (Figure 4).

Early removal due to cramping pain occurs frequently and more often in nulliparous and adolescent women than in older women. Discontinuation rates after 6-12 months of use of 40 to 50% are not atypical [17]. Early discontinuation places these young women at risk of unintended pregnancy as many among them move to less effective methods or to no protection at all. More importantly, these women will rarely return to intrauterine contraception. They are also spreading bad publicity about the method. Early discontinuation serves to undermine the clear contraceptive advantages of IUDs with a subpopulation of

patient comfort while minimizing the risk of expulsion is unknown. In our study we found only 3 women who had maximal fundal widths greater than 32 mm. A critical, but yet unknown balance is required for T-shaped devices capable of long term comfort and retention.

Figure 5 shows uteri of nulliparous women with much different IUD cavity widths, examples of uteri from our daily practices. Most nulliparous women (~80%) in our study had a uterine cavity between 15 mm and 28 mm. What is readily apparent from our study using 3D ultrasound, not only is the size of the uterine cavity variable amongst nulliparous women, so is its shape. Few had uterine shapes comparable to those illustrated in medical textbooks and advertisements.

Conventional T-shaped IUDs are limited by their requirement that they have a transverse arm in order to maintain retention within the uterine cavity. An alternate approach for retention, which eliminates the need entirely for any transverse arm, and can be inserted in any size or shape uterine cavity, is the frameless GyneFix® in (Control, Ghent, Belgium), marketed as a unique copper device capable of a high degree of effectiveness and high patient acceptance [20]. It utilizes free moving multiple copper cylinders around a nonabsorable suture allowing it to fit different sizes and shapes of the uterus. Its small size, narrow dimensions (2.2 mm) and its flexible nature once inserted allows it to readily adapt to changes in the uterine cavity. In contrast to conventional T-shaped framed IUDs, frameless IUDs maintain a high rate of continuation over the full lifespan of the IUD. Patient continuation rates for frameless devices appear to be substantially greater than that seen for framed systems with continuation rates being reported of over 90% at 5 years [21,22]. Figure 6 shows hysteroscopic views of the frameless GyneFix IUD in a small cavity in comparison with the Mirena IUD inserted in a sufficiently wide uterine cavity. From these pictures, it is clear that the framed Mirena IUD will likely be deformed, expelled or embed if it were inserted in a uterine cavity which is not wide enough. Discrepancy between the size of the IUD and that of the uterine cavity explains the many discontinuations reported in clinical studies in young women [8-13]. In our study several women (0.7%) had maximal fundal widths below 10 mm who had the frameless IUD.

The recent introduction of Jaydess/Skyla with a transverse arm of 28 mm is positioned for shorter term use (3 years) in younger women. Although data is still being acquired the patient continuation rates for Jaydess over its 3 year lifespan is ~70 to 75%, a value consistent with the annual discontinuation rate of 10-15% seen with larger devices [23]. Discontinuation rates of ~17% have been reported in one study over a 12 month period in 304 adolescent girls [24]. Even the more recently introduced intrauterine ball device which relies on the use of a memory wire to maintaining shape may provide an option, but recent data suggest that expulsion and request for removal for this device are approaching 50% of participants [25].

The strength of the present study is that 3D measurements were performed by competent sonographers with a great deal of experience in 3D sonography and the use of adequate equipment by all investigators. 3D ultrasound is generally recognized as the gold standard for the evaluation of the uterine cavity. The ability to conduct sonographic measurements in most gynecological practices and clinics affords the clinician an opportunity to assess the suitability of the uterine cavity prior to as well as immediately post insertion and with minimal inconvenience. Our experience also suggests that either 2D or 3D ultrasound are suitable. The boundaries of the uterine cavity can be accurately visualized premenstrual with 2D ultrasound although instillation of gel may be necessary in the first half of the menstrual cycle. Instillation with Instillagel® (Farco Pharma, Köln, Germany) allows mostly good visibility and clear definition of the uterine cavity boundaries (Figure 7).

3D ultrasonography, however, has added advantages in its ability to fully visualize the entire cavity and IUD simultaneously. It affords the gynecologists the ability to routinely check placement not only at placement but follow-up visits. As utilization of sonography occurs, and physicians become more aware of the importance of uterine cavity with respect to IUD selection, more information on suitable limits with respect to IUD size and shape can be generated.

There are some minimal discrepancies between our measurements of the mean uterine cavity width with those found in previous studies using 2D ultrasound or a measuring instrument (Cavimeter®) [18-19]. However, there is little doubt that the maximal uterine fundal width of most women is much less than first believed. The overall uniformity of our data across independent centers serves to further substantiate the findings.

3D ultrasound and hysteroscopy are the best methods to visualize and evaluate the suitability of IUD in the presence of acquired or congenital anomalies of the uterus. With respect to uterine suitability, uterine anomalies such as uterus arcuatus or a partial septate uterus may reduce the available space in the uterus for conventional IUDs further (Figure 8). These mullerian anomalies are probably more
frequent than the incidence of 5% mentioned in the literature [26,27]. It should be noted that bimanual examination is not useful to assess the size of the uterine cavity as there is no relationship between the size of the body of the uterus and the size of the uterine cavity [28].

Summary statement

Conventional IUDs are generally too large for uterine cavities of nulliparous women (and many parous women). The use of appropriate intrauterine devices that take into account the geometric relationship of the device to the host uterine cavity will likely result in high rates of continuation due to greater patient comfort leading to fewer unintended pregnancies and induced abortions. At least 2D, preferable 3D equipment, as well as highly trained health care providers, should be available at all sites providing intrauterine contraception as the assessment of a patient’s uterine cavity size is essential in the selection of an appropriate IUD. When selecting a framed IUD, consideration to uterine compatibility should be made. It is evident that measurement of the cavity width is not necessary with the frameless IUD. Routine and repeat ultrasound confirmation of IUD placement, whether 2D or 3D, should be made in an effort to maximize patient comfort.

Conflict of interest

Kilian Nolte, MD, Sohela Jandi, MD, Olivier Julen, MD, Thomas Hasskamp, MD: nil. Dirk Wildemeersch, MD, PhD has conducted research in the field of non-hormonal and hormonal, framed and frameless intrauterine devices, including in nulliparous and adolescent women, since more than 20 years and is the inventor of the GyneFix IUD. He did not receive any financial compensation of any kind.
