Can Squamous cell carcinoma affect young healthy adults? 
case report of oral squamous cell carcinoma of the tongue in 19-year-old female

Abstract
Squamous cell carcinoma is the most common malignancy in the oral cavity. However, it rarely occurs in patients younger than 40 years of age. In this article, we report a rare case of squamous cell carcinoma of the tongue in a healthy 19-year-old female patient. This report highlights the etiological factors, diagnosis and prognosis of this case with a brief literature review.

Introduction
Oral squamous cell carcinoma (SCC) is the most common oral cancer, accounting for more than 90% of malignant lesions [1,2]. Worldwide, SCC is the eighth most common cancer in incidence with various geographic distributions [1]. It typically occurs in older age [3,4], during fifth – eighth decades of life [5]. In regard to the gender predominance, male are more affected by SCC [2,3,5,6]. The most commonly affected site is the tongue, with the preponderance to the posterior lateral border [3]. The lip and floor of the mouth are also common sites followed by soft palate, gingiva and buccal mucosa [2,7]. The epidemiology of SCC is greatly affected by the risk factors. Alcohol consumption, use of tobacco and betel quid chewing are considered major risk factors in older groups [2,8].

In this article we report a rare incidence of SCC in a young healthy female. This emphasizes the importance of including malignancy in the differential diagnosis of suspicious lesions in young patients.

Case report
This is a 19-years-old healthy female that presented with a non-healing ulcer for two months. Initially, the patient was seen in a private clinic and was prescribed antibiotics and analgesics with no improvement. The patient was then referred to the oral and maxillofacial surgery clinic in King Abdulaziz Medical City (KAMC) in Riyadh from her general dentist in the primary health care center. The patient had a negative history of tobacco and alcohol use. The patient had no family history of malignancy or of exposure to secondhand smoke. She had no history of systemic disease, previous trauma or extensive dental treatment except for orthodontic treatment. On examination, the patient had a painful ulcer on the left posterior side of the dorsum of the tongue measuring 3 x 4 cm with irregular and indurated margins. The surrounding mucosa was erythematosus with exophytic growth. (Figure 1) there was limitation in tongue movement with no difficulty in swallowing. Lymph nodes at level II on the left side were palpable.

A provisional diagnosis of traumatic ulcer was made. Differential diagnosis included traumatic ulcer, syphilis, and tuberculosis. Incisional biopsy was performed under general anesthesia with specimens from different sites of the lesion. The histopathology report shows infiltrating sheets of highly atypical squamous cells, consistent with moderately differentiated squamous cells carcinoma (Figure 2). In a view of this diagnosis, computed tomography (CT) was done for the face, abdomen and chest and showed an enhanced soft tissue mass measuring 3x4cm in the left tongue (Figure 3-A) pathological necrotic lymph node at level 2 A (Figure 3-B) and a small nodule measuring 1.3 cm x 0.8 cm in the right breast. Lung and abdomen were clear with no nodules or masses. PET scan and head and neck MRI revealed a left hypermetabolic tongue lesion approaching the midline and extending to the floor of mouth, metastatic left neck level II A and level IB lymph nodes (Figure 4-A, B).

Figure 1. Ulcerative lesion on the left posterior side of the dorsum of the tongue.
Papilloma virus in-situ hybridization studies (HPV-ISH) were not dissection lymph nodes was identified. Attempts to do the Human cm) into three lymph nodes out of seventy-three total bilateral neck carcinom. Foci of tumor metastasis (ranging from 0.5 cm up to 1.5 was identified. Left sublingual gland was positive for squamous cell were free of tumor. Extensive lymphovascular and perineural invasion was identified. Left sublingual gland was positive for squamous cell carcinoma. Foci of tumor metastasis (ranging from 0.5 cm up to 1.5 cm) into three lymph nodes out of seventy-three total bilateral neck dissection lymph nodes was identified. Attempts to do the Human Papilloma virus in-situ hybridization studies (HPV-ISH) were not successful due to the unavailability in our institution at the present time.

Following the surgical treatment, the patient was referred to the oncology department in KAMC for chemo- and radiotherapy. The patient received a radiation dose of 66Gy in 33 fractions with chemotherapy of Cetuximab over a period of 6 weeks. At the end of the treatment, the patient developed grade III mucositis, grade II dermatitis and burning sensation in the skin over the chin. The patient also suffered from weight loss and nutritional deficiency.

**Discussion**

SCC is rare in young adults with a percentage of 1 to 6% [3]. Interestingly, in recent years there has been an increase in incidence worldwide. The percentage of SCC of the tongue in young adults increased from 3% in 1973 to 6% in 1993. In Saudi Arabia, Oral cancer appears to represent 4.3 to 17.8% of all registered cancers with a steady increase in incidence in the last decade [9].

In previous literature, when comparing SCC in young adults with groups over the age of 40, some differences have been described. Looking at the gender distribution, younger groups showed equal sex predilection, whereas the older patients showed higher incidence in males [10,11]. Both age groups have the same clinical presentation with no distinguishing features [3,5]. Several authors reported a more aggressive behavior of SCC in younger patients with poorer prognosis [10,11].

The most common risk factors of SCC are alcohol and smoking; however this is a controversial topic in young adults. Some authors argue that these risks factors are not applicable in this age group for two reasons. First, the incidence of smoking and alcohol consumption in this group is low; secondly if present the exposure time is relatively short to cause a malignant transformation [3,10,12]. Other factors associated with SCC include viral infections caused by Human Papilloma virus (HPV) and Epstein-Barr viruses (EBV) [3,10].

Some authors suggest an association between SSC and immunodeficiency states in younger patients [8, 10]. In this age group, there has been an association between SCC and genetic conditions such as Fanconi’s anemia, xeroderma pigmentosum, keratitis, ichthyosis immunodeficiency states in younger patients [8, 10]. In this age group, there has been an association between SCC and genetic conditions such as Fanconi’s anemia, xeroderma pigmentosum, keratitis, ichthyosis and deafness (KID) syndrome [7,11].

In this article, we report a case of tongue SCC in a 19-year-old female with a negative history for smoking and alcohol consumption. Her past medical history and family history were not significant. The most elucidating factor for a justification of SCC in this patient was chronic trauma from her previous orthodontic treatment. However, previous studies failed to prove that trauma alone can cause malignant transformation [5]. The presence of a premalignant lesion or HPV association cannot be ruled out in this case.

According to previous studies, the tongue is the most common site of oral SCC in the young patients [13]. In 2000, Oliver et al reported 3 cases of oral SCC in the tongue, all affecting patients below the age of 30. The first case reported a 26-year-old male medically free but presented with a sore area in the left side of his tongue. Diagnosis of SCC was confirmed with a biopsy and the patient underwent total excision only. The patient was followed for 5 years with no evidence of recurrence. The second case was a 24-year-old female that presented with a lump under her tongue with lymph node evolvement. Following surgical treatment, the patient received radiotherapy and remained disease free for 5 years. The last case reported a 20-year-old female with ulcerative...
lesion in the lateral border of the tongue with lymph node involvement. Patient was treated with surgical resection and radiotherapy however she died 5.5 months later [14].

In this case, the patient underwent surgical treatment which consisted of subtotal glossectomy, reconstruction with left radial forearm flap, bilateral neck dissection and marginal mandibulectomy followed by concurrent radiotherapy and chemotherapy. The patient is under regular follow up with the oncology department and nutritional department.

Conclusion

Clinicians should include SCC in their differential diagnosis of suspicious lesions regardless of its rare occurrence in young patients. A non-healing lesion should be biopsied as early as possible, as the prognosis of SCC is affected by the early diagnosis.
